We present a series expansion study of spin- S square-lattice Heisenberg antiferromagnets. The numerical data are in excellent agreement with recent neutron scattering measurements. Our key result is that the correlation length ξ for $S > 1/2$ strongly deviates from the exact $T \rightarrow 0$ (renormalized classical, or RC) scaling prediction for all experimentally and numerically accessible temperatures. We note basic trends with S of the experimental and series expansion correlation length data and propose a scaling crossover scenario to explain them.

In recent years much attention has focused on two-dimensional (2D) square-lattice quantum Heisenberg antiferromagnets, described by the Hamiltonian

$$H = J \sum_{\langle ij \rangle} \mathbf{S}_i \mathbf{S}_j, \quad (1)$$

where $\langle ij \rangle$ denotes summation over all pairs of nearest neighbors. In their seminal work [1], Chakravarty, Halperin, and Nelson (CHN), utilizing a mapping of the low-energy spectrum of Eq.(1) onto the quantum nonlinear sigma model (QNL σ M), have shown that the low-temperature properties of these systems obey renormalized classical (RC) scaling, where the correlation length $\xi \approx 0.37 \times (c/\rho_s) \exp(2\pi\rho_s/T)$ for $T \ll \rho_s$ (here ρ_s is the $T \rightarrow 0$ spin stiffness, and c is the spin-wave velocity). Subsequently, Hasenfratz and Niedermayer calculated for the 2D QNL σ M the exact value of the prefactor and the leading $O(T/2\pi\rho_s)$ correction [2]:

$$\xi_{\text{HN}} = \frac{e}{8} \frac{c}{2\pi\rho_s} \exp\left(\frac{2\pi\rho_s}{T}\right) \left[1 - \frac{T}{4\pi\rho_s} + O\left(\frac{T}{2\pi\rho_s}\right)^2\right], \quad (2)$$

The neutron scattering measurements of $\xi(T)$ in $S = 1/2$ layered Heisenberg antiferromagnets such as La_2CuO_4 [3] and $\text{Sr}_2\text{CuO}_2\text{Cl}_2$ [4] reveal a remarkable agreement with Eq.(2). At first sight, one would expect the RC description to improve as the value of the spin increases. If S is formally regarded as a continuous variable, then the Néel order is expected to vanish for some $S < 1/2$. At the critical point, where ρ_s vanishes, Eq.(2) fails and the correlation length is, in fact, inversely proportional to the temperature; this is the quantum critical regime (QC), discussed in Ref. [1,5] (it was argued earlier [5,6] that the $S = 1/2$ Heisenberg model (1) exhibits certain signatures of QC behavior for $T > 0.5J$; we do not discuss RC to QC crossover effects in this letter). Naively, increasing the value of spin moves the system

away from this limit so that the RC behavior would be more pronounced.

FIG. 1. Semi-log plot of the series expansion result for the correlation length in the $S = 1$ Heisenberg antiferromagnet versus T/J (solid line) together with the experimental data for K_2NiF_4 (solid circles, [4]) and La_2NiO_4 (open circles, [7]). Numerical and experimental results agree with each other, and all deviate from the exact RC prediction [2] evaluated using known values for c and ρ_s [8,9] (dashed line).

However, such an expectation does not hold. Recently, Greven and co-workers [4,7] have reported a significant discrepancy between the neutron scattering measurements of the correlation length in the $S = 1$ systems

K_2NiF_4 and La_2NiO_4 and the RC prediction. Preliminary experiments on the $S = 5/2$ system Rb_2MnF_4 reveal an even larger discrepancy [10]. As is evident from Fig.1, our series expansion result for $S = 1$ [11] is in excellent agreement with the experimental data in the region of overlap, and also deviates substantially from the RC prediction (note, that ξ is expressed in units of the lattice constant a).

In order to investigate the origin of this deviation, we have calculated high-temperature expansions for the Fourier transform of the spin-spin correlation function $\langle S_{-\mathbf{q}}^z S_{\mathbf{q}}^z \rangle$ for all spins in the range $S = 1/2$ to $S = 5/2$. The generation of the series expansions will be discussed elsewhere. We present the data for the $T = 0$ structure factor $S_0 = S(\mathbf{Q})$, where $\mathbf{Q} = (\pi/a, \pi/a)$ is the staggered ordering wavevector, and the second moment correlation length ξ is defined by $\xi^2 = -(\partial^2 S(\mathbf{Q} + \mathbf{q})/\partial q^2)|_{q=0}/2S_0$. The series are analyzed by either performing direct Padé approximation or by taking the logarithm of the series first and then calculating the Padé approximants. The latter is likely to show better convergence if the correlation length increases exponentially fast at low temperatures. We restrict ourselves to temperature ranges where different methods of extrapolation agree within a few per cent.

FIG. 2. Series expansion results for the correlation length plotted as ξ/ξ_{HN} versus T/ρ_s . Here ξ_{HN} is the exact RC prediction [2], Eq.(2), with c and ρ_s from Ref. [8,9]. The ratio ξ/ξ_{HN} , which is fairly close to unity for $S = 1/2$, gradually decreases as S increases, suggesting increasing disagreement with RC theory for larger S .

The ratio between the calculated ξ and the Hasenfratz and Niedermayer formula ξ_{HN} given by Eq.(2), is plotted in Fig.2 for different spins as a function of T/ρ_s . Contrary to the naive expectation that the RC behavior becomes more pronounced as S increases, we find that for the range of temperatures probed here ξ monotonically deviates from ξ_{HN} as S increases. As noted above, this same systematic trend is seen experimentally [3,4,7,10].

FIG. 3. Semi-log plot of $S\xi/a$ versus T/JS^2 of $\text{Sr}_2\text{CuO}_2\text{Cl}_2$ ($S = 1/2$, open circles, [4]) and K_2NiF_4 ($S = 1$, solid squares, [4]) together with the series expansion results ($1/2 \leq S \leq 5/2$, represented by the various lines) as well as Monte Carlo data ($S = 1/2$, solid squares, [12]). However impressive, this data collapse is inconsistent with Eq.(2) with c and ρ_s from Ref. [8].

In an attempt to understand these data, we have considered various possible scaling scenarios. To highlight the expected spin dependence, we note that for a square-lattice nearest-neighbor Heisenberg antiferromagnet, $\rho_s = Z_\rho(S)JS^2$ and $c = 2^{3/2}aZ_c(S)JS$. The quantum renormalization factors $Z_\rho(S)$ and $Z_c(S)$ are known from spin-wave theory [8] (for all values of S), $T = 0$ series expansion [9] (for $S = 1/2$ and $S = 1$), and Monte Carlo studies [13] (for $S = 1/2$). For $S = 1/2$ and $S = 1$ these different methods yield good agreement.

Eq.(2) may then be written as

$$\frac{S\xi}{a} = \frac{eZ_c}{2^{5/2}\pi Z_\rho} \exp\left(\frac{2\pi Z_\rho}{T/JS^2}\right) \left[1 - \frac{T/JS^2}{4\pi Z_\rho} + \dots\right], \quad (3)$$

which suggests plotting $S\xi/a$ versus T/JS^2 to elucidate

the dependence on S . The results so-obtained are shown in Fig.3. For $S = 1/2$ we also show Monte Carlo data [12], which extend to somewhat lower temperatures than the series expansion result. Surprisingly, over the range of $S\xi/a$ from 1 to at least 50, the data to a good approximation fall on the same curve. For the sake of clarity, we have omitted experimental data for La_2CuO_4 ($S = 1/2$), La_2NiO_4 ($S = 1$), and Rb_2MnF_4 ($S = 5/2$), all of which fall on the approximate “scaling” curve of Fig. 3 to within experimental error.

It was demonstrated in Ref. [4] that Eq.(3) describes the correlation length data in absolute units in the $S = 1/2$ system $\text{Sr}_2\text{CuO}_2\text{Cl}_2$ extremely well. Interpreted naively, Fig.3 would then suggest that RC behavior holds for all S , but with quantum renormalization factors $Z_\rho(S)$ and $Z_c(S)$ that are nearly S -independent for $1/2 \leq S \leq 5/2$ and close to their values at $S = 1/2$, $Z_\rho(1/2) \approx 0.72$ and $Z_c(1/2) \approx 1.2$. *However, this is very unlikely.* Spin-wave theory [8] predicts a substantial S -dependence: $Z_\rho(5/2) \approx 0.95$ and $Z_c(5/2) \approx 1.03$, which is already close to the classical limit ($S \rightarrow \infty$) in which $Z_\rho, Z_c \rightarrow 1$. Serious errors in these values seem very unlikely, given their good agreement for $S = 1/2$ and $S = 1$ with those obtained by other methods [9,13].

In an attempt to understand these data, it is helpful to recall that at any fixed T/ρ_s RC theory will inevitably fail for sufficiently large values of spin. Indeed, a straightforward application of Eq.(2) to the $S \rightarrow \infty$ limit taken at $T/JS^2 \sim 1$ would predict $\xi = 0$. However, the above limit corresponds to the classical Heisenberg magnet, where ξ/a is known to be finite and of order unity for $T \sim JS^2$.

One can understand *where* Eq.(2) may fail by following CHN in their derivation of the leading asymptotic behavior in the RC regime, but taking into account that S may be large. CHN have shown that for $T \ll \rho_s$ the magnetic correlations can be calculated using classical dynamics, except that all wavevector integrations should be limited to $|\mathbf{q}| \lesssim q_c = T/c$ rather than taken over the whole Brillouin zone. Here the words “classical dynamics” simply mean that for $|\mathbf{q}| \lesssim q_c$, all Bose factors for spin-waves can be approximated assuming $cq \ll T$. The key result of CHN is to show that such a calculation yields the correct spin correlations for the quantum Heisenberg model. We now evaluate the cutoff wavevector as

$$q_c \sim \frac{T}{c} \sim \frac{\rho_s}{c} \frac{T}{\rho_s} \sim \frac{S}{a} \frac{T}{\rho_s}. \quad (4)$$

This dependence of q_c on S arises because the spin stiffness is proportional to the square of S , but the spin-wave velocity is only linear in S .

For $S \gg 1$ and $T \sim \rho_s \sim JS^2$, the cutoff wavevector $q_c \sim S/a \gg \pi/a$ is *outside* the Brillouin zone. Hence, the requirement that $cq \lesssim T$, or equivalently $q \lesssim q_c$, places no further restrictions on the q -integrations which are already limited by the Brillouin zone. In this case

all of the integrals are the same as those of the classical Heisenberg magnet, and the classical $S \rightarrow \infty$ limit is recovered.

The crossover temperature T_{cr} between the RC and classical regimes depends on S , and its order of magnitude can be estimated as the temperature where $q_c \sim a^{-1}$. This yields

$$T_{cr} \sim \frac{c}{a} \sim JS, \quad \text{while } \rho_s \sim JS^2. \quad (5)$$

By substituting T_{cr} into Eq.(2), one concludes that the crossover from RC behavior at low temperatures to classical behavior at higher temperatures should occur for a $\xi_{cr} = \xi(T_{cr})$ that is larger for larger S .

FIG. 4. Semi-log plot of the correlation length obtained from series expansion plotted versus $T/(JS(S+1))$ for $S = 1/2, 1$, and $5/2$. For larger spins ξ/a is close to the classical ($S \rightarrow \infty$) limit, which provides evidence that classical ($S \rightarrow \infty$) magnetic behavior holds for $JS \ll T \ll JS^2$, in agreement with our proposed scaling crossover scenario. Note, that in most of the temperature range shown, the $S \rightarrow \infty$ model is not in the scaling limit and its correlation length deviates from the expected $T \rightarrow 0$ behavior $\xi/a \approx \text{const} \times (T/JS^2) \exp(2\pi JS^2/T)$.

In order to test this scenario, we plot the correlation length as a function of $T/(JS(S+1))$ in Fig.4, where $JS(S+1)$ is the *classical* (not $T = 0$) spin stiffness. In replacing S^2 by $S(S+1)$, we follow a purely empirical observation that the correlation length at $T \gg JS$ for $S > 3/2$ seems to depend on S primarily through the combination $S(S+1)$ (for $T \ll JS$, ξ depends on S only

through ρ_s and c). We find that ξ gradually approaches the classical result as S increases, and the difference between ξ for the largest spin in our study ($S = 5/2$) and the classical antiferromagnet ($S \rightarrow \infty$) is already very small. This result supports the hypothesis that the deviations from asymptotic RC behavior evident in Figs. 1 and 2 are driven primarily by RC to classical crossover effects.

Another important observable of the scaling theory is the Lorentzian amplitude of the spin-spin correlator, S_0/ξ^2 , where S_0 is the correlator magnitude at $Q = (\pi/a, \pi/a)$. This ratio has only a power-law temperature dependence, and is therefore less sensitive to the model parameters than ξ or S_0 separately. A detailed discussion of this quantity is beyond the scope of this publication. However, we note some important issues which need to be clarified before the scaling behavior of S_0/ξ^2 can be fully understood.

The RC scaling prediction for this quantity is [1]

$$\frac{S_0}{\xi^2} = Z_3 \frac{N_0^2}{2\pi} \left(\frac{T}{\rho_s} \right)^2, \quad (6)$$

where Z_3 is a universal number and N_0 is the $T = 0$ sublattice magnetization defined such that in the classical ($S \rightarrow \infty$) limit $N_0 = S$, and S_0 is defined such that $S_0 = S(S+1)/3$ for $T \rightarrow \infty$. The value of Z_3 can be estimated independently using the numerical data for the two limiting cases $S = 1/2$ [11,12] and $S \rightarrow \infty$ [14,15].

Z_3 is estimated by substituting series expansion data at the lowest temperature where calculation is possible, $T_{\min}$, into Eq.(6). The data so-obtained for $S = 1/2$ and $S \rightarrow \infty$ differ by a factor of two: $Z_3 \approx 3.2$ for $S = 1/2$ when estimated at $T_{\min} = 0.35J$, and $Z_3 \approx 6.6$ for $S \rightarrow \infty$ when estimated at $T_{\min} \simeq 0.8JS^2$. The disagreement of the $S = 1/2$ and $S \rightarrow \infty$ results for this universal parameter suggests that at least one of the models is not in the scaling limit at the respective $T_{\min}$ [16].

Here we speculate on two possible causes of this discrepancy. First, if the classical model is in the classical scaling limit and the $S = 1/2$ model is not in RC limit, this discrepancy may be due to the vicinity of the classical to RC crossover. In this case, $S_0/\xi^2 T^2$ for the $S = 1/2$ model should increase at temperatures lower than those studied numerically, in order to reach its presumed larger scaling limit for $T \rightarrow 0$. This scenario may be consistent with neutron scattering measurements which give $S_0/\xi^2 \sim \text{const}$ [3,4,7].

Second, for either of the models the true $T \rightarrow 0$ scaling form for large $q\xi$ (q is a deviation from $\mathbf{Q} = (\pi/a, \pi/a)$),

$$S(\mathbf{q}) \simeq S_0 \frac{1 + (B_f/2) \log(1 + q^2 \xi^2)}{1 + q^2 \xi^2}, \quad (7)$$

and the hydrodynamic result, valid for $\xi^{-1} \ll q \ll T/c$,

$$S(q) \approx \frac{2}{3} \frac{TN_0^2}{\rho_s q^2}, \quad (8)$$

cannot hold simultaneously at the temperatures studied for any $\mathbf{q}$ inside the Brillouin zone. The reason is that the RC scaling form (7), which has to match the hydrodynamic expression (8) for $q\xi \rightarrow \infty$, is numerically found [11,15] to approach its asymptotic large- q limit quite slowly. In the temperature range studied, it still has large deviations from this limit for any $\mathbf{q}$ inside the Brillouin zone ($q \lesssim a^{-1}$), hence Eqs.(7) and (8) are not equal and at least one of them must be inconsistent with the data.

However, both Eqs.(7) and (8) are derived using essentially the same assumptions that (i) $c/\xi \ll T$ and that (ii) T is much smaller than other energy scales. This might indicate the importance of lattice corrections (i.e. finite size of the Brillouin zone) to the ratio S_0/ξ^2 in the temperature range studied, in which ξ is itself consistent with our proposed crossover scaling scenario for any S .

In summary, we present and analyze high-temperature series expansion data for the spin- S square-lattice Heisenberg model for all S in the range $S = 1/2$ to $S = 5/2$. In agreement with neutron scattering measurements, we find that the correlation length deviates from the low-temperature RC prediction of Eq.(2) for $S > 1/2$, and that the deviation becomes larger for larger S . We suggest that this deviation primarily reflects a crossover to classical (as opposed to *renormalized* classical, or RC) behavior in the temperature range $c/a \ll T \ll \rho_s$, or equivalently $JS \ll T \ll JS^2$, where the correlation length is nearly equal to that of the classical $S \rightarrow \infty$ model. In a subsequent publication [17], which is now in preparation, we propose to use comparisons between AFMs and FMs with the same value of S to study the role of quantum effects as a function of spin; the results obtained in [17] using this method are consistent with the crossover scenario proposed here. Finally, we discuss the behavior of the staggered structure factor S_0 , which measures the strength of magnetic correlations, and speculate on possible causes of its apparent deviation from the $T \rightarrow 0$ scaling limit.
